A gluco-mindful approach to diabetic gastroparesis
Sanjay Kalra¹, Saptarshi Bhattacharya², Hitesh Punyani³

Abstract
Diabetes gastroparesis is a common manifestation of autonomic neuropathy in persons with long-standing, uncontrolled diabetes. Most discussion about its management revolves around the mitigation of symptoms. Here, we share tips on choosing the right glucose-lowering medication, based upon predominant symptomatology of gastroparesis. We highlight how insulin preparations, and their timing of administration, can be tailored according to need. We also emphasize the need to choose oral glucose lowering drugs with care.

Introduction
Diabetic gastroparesis is a manifestation of autonomic neuropathy, which is often encountered in long-standing diabetes, along with other microvascular complications. The prevalence is higher in type 1 diabetes, and in women. The bidirectional link between gastroparesis and glycaemia is well known.¹ However symptoms of gastroparesis, viz, early satiety, nausea, bloating, abdominal pain and vomiting, once established, do not resolve with glycaemic control. Rather, the presence of these symptoms may confound or complicate efforts to manage glucose in a safe and secure manner.²

Much progress has been made in the study of gastroparesis, even though “the cupboard still seems bare”.³ The Gastroparesis Clinical Research Consortium works to understand the pathophysiology of the condition and develop effective treatments for it.⁴ The American Gastroenterology Association⁵ suggests that “clinicians should classify patients with gastroparesis into mild, moderate or severe, based on symptoms and the results of a properly performed gastric emptying study. AGA suggests symptom-based treatment while enjoining clinicians to be aware of multiple treatment options for nausea, vomiting and abdominal pain.

This approach should not be limited to choice of symptom-relieving medication. The same effort should be extended to choice of glucose lowering therapy as well. A wide spectrum of injectable and non-injectable drugs is now available, and the clinician should be cognizant of their pharmacokinetic properties and possible side effects. Persons with mild intermittent symptoms may benefit from avoidance or reduction in dose of drugs with gastrointestinal side effects, such as high dose metformin, alpha glucosidase inhibitors and glucagon-like peptide-1 receptor agonists (GLP1RA).

Persons with predominant bloating and early satiety, i.e., delayed gastric emptying, should be aware that ultra-rapid acting insulin analogues, with their fast onset of action, may cause post-prandial hypoglycaemia, and pre-prandial hyperglycaemia. Those with predominant vomiting, however, may benefit from these preparations. FI Asp (fast acting aspart) and URLi (ultra rapid acting lispro) can be injected up to 20 minutes after a meal, and this flexibility offers great confidence to a person who is unsure of his or her meal intake and absorption.⁶ One can first consume a meal, and then decide the dose of bolus insulin, based on carbohydrate counting and gastrointestinal tolerance.

There are at least two scoring scales for gastroparesis, including the validated Gastroparesis Cardinal Symptom Index.⁷ The American Motility Society Task Force on Gastroparesis scoring system⁸ proposes symptom-based guidelines for treatment of diabetic gastroparesis, based upon the clinical severity. We suggest a modified ‘gluco-mindful’ system which is more relevant to diabetes care providers, as well as persons living with diabetes. This helps not only in assessing severity, but also in planning appropriate therapy.
